SÚHRN

Najdôležitejšou abnormalitou aortálneho oblúka je bez diskusie prítomnosť artérie lusorie, aberantnej pravej artérie subclaviae. Práve prítomnosť tejto anatomickej štruktúry je často spätá s príznakmi spôsobenými útlakom jej okolia. Táto anomalia sa zriedkavo spája aj s prítomnosťou aneurizmy v mieste jej odstupu z aortálneho oblúka – Kommerellovho divertikulu, ktorý nesie riziko ruptúry alebo disekcie. Prezentujeme vzácný prípad 84-ročnej pacientky s asymptomatickou aneurizmom artérie lusorie, ktorá bolo diagnostikovaná náhodou počas hospitalizácie s následným endovaskulárny ošetrením.

ABSTRACT

The most important abnormality of the aortic arch is, without question, the presence of the arteria lusoria, the aberrant right subclavian artery (ARSA). The presence of this anatomical structure is often connected with symptoms caused by oppression in its surroundings. This anomaly is rarely associated with the presence of an aneurysm at the point of separation from the aortic arch – Kommerell's diverticulum, which carries the risk of rupture or dissection. We present a rare case of an 84-year-old patient with asymptomatic arteria lusoria aneurysm which was diagnosed by chance during hospitalization with subsequent endovascular treatment. Arteria lusoria and Kommerell's diverticulum were successfully endovascularly treated, resulting in good recovery.

Introduction

An obligatory abnormality of the aortic arch is the presence of the arteria lusoria (AL), which occurs in 0.7–2.0% population.¹ AL is the name for the aberrant right subclavian artery (ARSA), which comes out as the last branch of the aortic arch behind the left subclavian artery. In the presence of the ARSA the brachiocephalic trunk is missing, and four large arteries are emanating from the arch of the aorta (ARSA, right common carotid artery, left common carotid artery, left subclavian artery). This artery is passing in 80–84% of cases² through the posterior mediastinum, usually behind the oesophagus and often causes

its compression. Dysphagia caused by AL is called dysphagia lusoria.³ Rarely (12.7–15%) AL is running between the oesophagus and trachea, thus compressing the airways and causes a prolonged cough. In 4.2–5% of patients, AL is pre-tracheal.³ Origin of the AL can also suppress the left recurrent laryngeal nerve and lead to the development of Ortner's syndrome. It is this symptomatology that leads to the patient being sent for examination in order to exclude the oncological process. Other symptoms may include retrosternal pain, weight loss, and claudication.⁴ In most cases AL is asymptomatic and an accidental finding during autopsy, often associated with other aortic arch abnormalities. Kommerell's diverticulum (KD) is a very rare

congenital anomaly and is characterized as aneurysmal dilatation of the ARSA at the beginning of its origin.⁵ KD is associated with high risk of rupture or dissection. In this article we are presenting the case of a patient with AL and KD with an endovascular treatment.

Case study

The 84-year-old patient was admitted to our department for epigastric pain and hemodynamically insignificant enterorrhhea. Her medical history included ischemic heart disease, type 2 diabetes mellitus, arterial hypertension, chronic kidney disease and medical records of dysphagia in previous examinations at the emergency department. Her recent medical treatment included a beta-blocker and sartan for the treatment of hypertension and oral antidiabetics for the treatment of type 2 diabetes mellitus. As a part of the initial examination, a chest radiograph was performed with the finding of suspected aneurysmal dilatation of the aorta or possibly another mediastinal lesion (Fig. 1). At the time of the admission to the hospital, her blood tests showed only moderate-grade normocytic anaemia. A colonoscopy examination was performed with the finding of severe diverticulosis from the anus to

A black and white chest radiograph showing the thoracic cavity. A blue arrow points to a faint, irregular density in the upper mediastinum, which is a common presentation of an aortic aneurysm or other mediastinal masses.

Fig. 1 – Chest radiograph with the finding of suspected aneurysmal dilatation of the aorta or possibly another mediastinal lesion.

ileal flexion, some diverticula were still actively bleeding during the examination, and this condition was assessed by surgeons as diverticulosis with a recommendation for conservative treatment without surgery and for hemosubstitution and hemostyptic treatment. For suspected aortic aneurysm, computed tomography (CT) thorax angiography was performed. The finding of the CT angiography was aberrant right subclavian artery (AL) with a fusiform aneurysmal extension present from the origin from the aortic arch with a maximum width of 55 mm and with the presence of a wall thrombus in the aneurysm extension (Fig. 2). AL was passing retroesophageal and deviated the oesophagus to the right. Vascular surgeons and radiologists recommended endovascular treatment of the thoracic aorta using a stent graft with an occlusion of ARSA distal to the aneurysm by occluders (Fig. 3). The pro-

A grayscale axial slice from a CT thorax angiogram. It shows the aortic arch and its branches. A large, irregularly shaped, dark gray area (the aneurysm) is visible originating from the aortic arch. Two arrows are present: a red arrow pointing to the top edge of the aneurysm and a blue arrow pointing to a bright, linear structure within the aneurysm lumen, representing a thrombus.

Fig. 2 – CT thorax angiography finds ARSA with a fusiform aneurysmal extension present from the origin from the aortic arch (Kommerell's diverticulum) with a maximum width of 55 mm and with the presence of a wall thrombus (18 mm) in the aneurysm extension.

cedure was performed by interventional radiologists. After the intervention, the patient was set for anticoagulant treatment and she has been monitored regularly.

Discussion

AL was first described in the literature in 1735 by Hunauld,⁶ the word *Iusoria* being formed from the Latin word *lusus naturae*, which means a trick of nature. AL is often dilated at the point of its separation and forms a diverticulum known as the Kommerell's diverticulum, first described by the German radiologist Burckhard F. Kommerell in 1936.⁷ In the literature, the incidence of this diverticulum in AL is described between 20 and 60%.^{3,6} Polgj et al. in his study of 141 cases showed the development of AL is more common in women than in men and that AL is symptomatic in only about 7–10% of cases.⁶ A higher presence of AL is associated with genetic syndromes such as Down's and Edwards' syndrome. According to Nakajima et al. there is a higher incidence of AL even in Fallot tetralogy.⁸ Symptoms usually occur in two periods, in childhood and in

A grayscale axial slice from a CT thorax angiogram showing the same anatomical area as Fig. 2. The aneurysm is still visible, but the internal thrombus is no longer present. The red and blue arrows are also present, indicating the location of the aneurysm relative to the aortic arch and the surrounding structures.

middle age. In children, the presence of AL usually manifests as cyanosis, stridor, and recurrent pneumonia due to underdeveloped trachea, which is easier to compress under AL pressure. In adults whose trachea is rigid and difficult to compress, this anomaly manifests as dysphagia. The mean age of patients diagnosed with symptomatic AL is 48 years.⁹ Diagnosis and differential diagnosis are based on imaging, radiographic findings, and thorax CT. Treatment is indicated for the symptomatic relief of dysphagia and for the prevention of complications due to aneurysmal dilatation. There is no clear link between the size of the diverticulum and the need for surgery. The most common diverticulum complications include rupture, dissection, and thrombosis.⁵ Conventional surgical treatment and endovascular intervention are used to treat this anomaly, and the advantages and disadvantages of each option are constantly discussed. Currently, endovascular treatment is the preferred choice because it does not require central anaesthesia, is less invasive, takes less time and also has a lower risk of high blood loss.^{10,11} However, endovascular treatment is only suitable for anatomical compatibility of AL with endovascular stent; otherwise the only option is open surgery.² At present, advances in endovascular techniques have led to a hybrid alternative with combined open surgical and endovascular therapy.^{12,13} The presence of AL can cause undesirable complications in transradial coronary interventions. According to the literature, only 60% of the procedures during which the transradial approach was used, were successfully completed when AL was present.¹⁴ Sometimes during transradial approach a dissection of the ARSA may occur, so it is important to pay attention particularly to procedure, choose anatomically appropriate diagnostic catheters and specific manoeuvres and be prepared to prompt treatment if it is required.¹⁵

Conclusion

The arteria lusoria is a rare congenital anomaly of the aortic arch, which is also associated with other anomalies. It should not be forgotten that this aberrant right subclavian artery can cause difficulties mimicking other diseases, and therefore in the differential diagnosis of dyspnoea, dysphagia, retrosternal pain or weight loss, this rare diagnosis should be considered. It is especially important not to forget this unique diagnosis when distinguishing from other causes of dysphagia.

Authors' contribution

All authors contributed equally to preparing the manuscript.

Conflict of interest

The authors state that there are no conflicts of interest regarding the publication of this article.
